## Preface

Deep appreciation is given to Cliff Vansickle for production of the electron gun and to Vivian E. Merchant for his help in the standardization procedure.

Special thanks is given to Max L. Lake for pulling me through despite my problems and to Alan Garscadden for pushing me through the thesis.

The author is extremely grateful to Joy Williams for her excellent typing abilities.

A large measure of profound gratitude is due my wife, Anne, for her patience and inspiration during the course of this work.

# List of Symbols

$N$	Number density of the gas
$A$	Area of the electron beam
$l$	Length of the interaction volume
$Q_i$	Cross sections in $\text{cm}^2$ of each atom in the area $A$
$N_e$	Electron number density
$v_e$	Electron velocity
$\sum_j F_{ij}$	De-excitation from $i^{\text{th}}$ state
$\sum_k F_{ki}$	Cascading into $i^{\text{th}}$ state
$\Delta X$	Width of Observation slit
$d$	Diameter of electron beam
$H$	Height of the observational volume
$F_{ij}$	Photon flux for one transition
$I$	Electron current
$e$	Electron charge
$A_{ij}$	Einstein coefficient for spontaneous emission from $i$ to $j$
$B_{ij}$	Branching factor for $i$ to $j$ transition
$Q_{ij}$	Optical cross section
$\Omega$	Solid angle
$F_{ij}(\Omega)$	Photon flux in certain solid angle
$S(\lambda)$	Spectrum Sensitivity
$t(\lambda)$	Transmission factor
$I_c$	Detector signal
$N_s$	Total current density of electrons

## Symbols

$m$	Mass of electrons
$v$	Electron velocity
$K$	Boltzmann's constant
$T$	Temperature in degrees Kelvin
$E$	Energy
$V_r$	Retarding potential
$\pi$	3.14159
$R$	Lens radius
$S_o$	Object distance
$t_m$	Monochromator transmission factor
$\lambda$	Wavelength
$\lambda_o$	Wavelength for peak transmission
$\Delta\lambda$	Monochromator bandpass
$t_w$	Transmission factor of chamber window
$t_L$	Transmission factor of standard lamp window
$P$	Spectral radiant flux
$R$	Spectral reflectance
$N$	Spectral of radiance
$S$	Area of spectrometer slit
$A$	Area of limiting optic
$D$	Distance of optic from slit
$A_S$	Area of tungsten ribbon
$\Omega_S$	Solid angle for standardization
$t_s$	Transmission factor of standar lamp window
$R_N(\lambda, T)$	Photon radiancy

### Symbols

$F_S$	Photon flux
$e(\lambda, T)$	Emissivity of tungsten ribbon
$R_N^B(\lambda, T)$	Blackbody photon radiancy
$h$	Plank's constant
$c$	Speed of light
$c_1$	Constant
$c_2$	Constant
$\psi_i$	Wave function for particle
$k_i$	Wave number for particle
$\theta$	Angle of incidence

Abstract

Electronic impact excitation functions were measured for xenon in a pressure region in the  $10^{-4}$  torr range. A one centimeter diameter electron beam was used to excite the gas atoms. The electron gun produced a current of approximately one milliamp. Measurements were made in the regions where the signal was linearly proportional to current and pressure.

Most of the xenon I cross sections were sharply peaked around 18 eV. Broader excitation functions were measured which had peak cross sections at electron energies around 30 eV. Cascading from higher energy levels showed significant effects on selected optical excitation functions.

Conditions enabled measurement of xenon II lines produced by simultaneous ionization/excitation. The xenon II excitation functions demonstrated a maximum at approximately 35 eV, and a broader shape than the Xe I  $5s \rightarrow 6p$  excitation functions.

## I. INTRODUCTION

Interaction between an electron beam and a volume of gas may lead to inelastic collisions such as ionization or excitation of the gas atoms. The probability that a given atom will exhibit a specific reaction due to a collision with a specific kind of incident particle and its energy can be formulated using a classical construct termed the cross section. Atomic or molecular cross sections for excitation to bound states can be determined by examining the wavelengths of light emitted after the interaction has occurred. Cross sections as a function of the bombardment energy are termed excitation functions and such data for specific lines are useful as a basis for development of lasing predictions for certain gases. They can also be used to determine the utility of a gas as a particular wavelength source. Cross sections are also needed for theoretical analysis of astrophysical phenomena.

Optical cross sections for excitation to states that radiate in visible regions of the spectrum have been measured for many of the noble gases. However, measurements of excitation cross sections for transitions with wavelengths in the infrared region are needed. These transitions have long wavelengths, typically 2-5 $\mu$ m. The infrared transitions are important in lasing applications. This experiment is necessary to complement the theoretical modeling and enhance knowledge of interactions in this region of study. Observations of xenon gas have shown that strong lasing lines exist for transitions which originate on all 5d levels and terminate on one of the 6p levels (refer to arrow in Figure 1). Electron collision is apparently the primary means of excitation (Ref. 1:39) and thus, this experiment has been devised to examine some of these transitions.

Figure 1. Energy Level Diagram of Xenon (Ref. 2).

## II. EXPERIMENTAL PROCEDURE

### Rate Equation

The equation describing the rate of population of the  $i^{\text{th}}$  state of the gas from electron impact is given by:

$$\frac{dN}{dt} = NA\ell \frac{Q_i}{A} \int N_e v_e dA' + \sum_k F_{ki} - \sum_j F_{ij} \pm \text{collisional terms} \quad (1)$$

where  $N$  is the number density of the gas,  $A$  is the area of the electron beam,  $\ell$  is the length of the interaction volume,  $Q_i$  is the cross section in  $\text{cm}^2$  of each atom in the area,  $N_e$  is the electron number density,  $v_e$  is the electron velocity,  $\sum_k F_{ki}$  denotes cascading into the  $i^{\text{th}}$  state, and  $\sum_j F_{ij}$  denotes excitation from the  $i^{\text{th}}$  state (Ref. 3). Figure 2 shows the relative positions of levels  $i$ ,  $j$ , and  $k$ . The interaction volume is the region of interaction between the electron beam and the gas. The interaction volume is well defined if it is assumed that the gas atoms are stationary compared to the electron velocity. The target chamber is filled with the target gas. Electron-electron collisions and charge repulsion in the interaction volume result in enlargement of the electron beam diameter, giving the beam a conical shape as shown in Figure 3. To account for this divergence, the observational volume must include all of the electron beam.

The observational volume is the region of the interaction volume from which radiation is collected. The two volumes are shown in Figure 3. The interaction volume is denoted by  $A\ell$  where  $A$  is the area of the electron beam at the center of the electron observational slit and  $\ell$  is the length of the target chamber. The observational volume is  $\Delta x H d$  where

Figure 2. Relative Energy Levels.

$\Delta x$  is the width of the observation slit,  $H$  is its height, and  $d$  is the diameter of the electron beam, assumed rotationally symmetric. The height,  $H$ , of the observational volume must be greater than the diameter,  $d$ , of the electron beam. This accounts for the divergence of the beam through the target chamber; and accomodates non-uniform current density as a function of electron velocity.

#### Cross Section Formula

The rate equation, Equation (1), can now be used to solve for the cross section,  $Q$ . At low pressure, less than  $10^{-3}$  torr, the collisional transfer term can be neglected because experiments (Ref. 3) have shown these not to be significant in the population scheme. After electron impact excitation for a sufficient period of time, depending on the

Figure 3. Interaction/Observational Volume.

lifetime of the observed state, the rate of change of the number of atoms in the  $i^{\text{th}}$  state goes to zero. Solving for the cross section of the  $i^{\text{th}}$  state gives:

$$Q_i = \frac{\sum_j F_{ij} - \sum_k F_{ki}}{N \lambda \int_A N_e v_e dA'} \quad (2)$$

This is termed the level cross section for the  $i^{\text{th}}$  state. The level cross section concerns all transitions out of a particular level and deletes cascade contributions. The optical cross section for a particular transition is given as:

$$Q_i = \frac{F_{ij}}{N \lambda \int_A N_e v_e dA'} \quad (3)$$

where  $F_{ij}$  is the photon flux for one transition. The optical cross section includes only the photon flux for a particular transition and has no cascade considerations. The photon flux can be measured by setting the monochromator to a specific transition wavelength.

It is necessary to express the cross section in terms of laboratory parameters. Once a workable formula has been derived, the cross section can be calculated for different electron energies. A curve which represents the cross section for state  $i$  as a function of electron energy is known as the excitation function for state  $i$ . The level cross section for the  $i^{\text{th}}$  state,  $Q_i$ , is given in square centimeters and is dependent on the energy of impacting electrons.

In the target chamber, the number of electrons per second which will suffer a collision with an atom in which that atom will end up in state  $i$  is  $N\ell Q_i \int_A N_e v_e dA'$  where  $\int_A N_e v_e dA'$  is the number of electrons passing through  $A$  each second. The current  $I$  can be expressed as,

$$I = e \int_A N_e v_e dA' . \quad (4)$$

Substitution gives the number of electrons per second suffering appropriate collisions as  $N Q_i I/e$ . Replacing  $\ell$  by  $\Delta x$  (because only radiation from the smaller region will be observed) and summing the photon flux yields:

$$N\Delta x Q_i I/e = \sum_j F_{ij} - \sum_k F_{ki} . \quad (5)$$

However, it is difficult to include all lines for transitions into and out of the  $i^{\text{th}}$  state. The photon flux for the transitions from state  $i$  to state  $j$  can be expressed as (Ref. 4:12),

$$F_{ij} = A_{ij} \int N_i A' dx , \quad (6)$$

where  $A_{ij}$  is the Einstein coefficient for spontaneous emission from  $i$  to  $j$ , and the integral is over the observational length of the electron beam. The total photon flux for all such transitions is

$$\sum_l F_i = \sum_l A_{il} \int N_i A' dx . \quad (7)$$

Combining the above two equations yields,

$$\sum_{\ell} F_i = \frac{\sum_{\ell} A_{i\ell}}{A_{ij}} F_{ij} \quad (8)$$

The term  $\sum_{\ell} A_{i\ell}/A_{ij}$  is called the branching factor of the  $i$  to  $j$  transition and can be denoted by  $B_{ij}$ . The total flux can be obtained by measuring the photon flux for one transition and by using the appropriate branching factor. Equation (5) then becomes:

$$N\Delta x Q_i I/e = F_{ij}/B_{ij} - \sum_k F_{ki} \quad (9)$$

This can be rewritten to give an expression for the direct cross section:

$$Q_i = \frac{1}{B_{ij}} \frac{F_{ij}}{N\Delta x I/e} - \sum_k \frac{F_{ki}}{N\Delta x I/e} \quad (10)$$

The cross section for a specific transition can be defined as,

$$Q_{ij} = \frac{e(F_{ij})}{N\Delta x I} \quad (11)$$

which is identical to Equation (3). Equation (11) is the optical cross section of the spectral line due to the transition from state  $i$  to state  $j$ . Substituting this into Equation (10) yields,

$$Q_i = \frac{Q_{ij}}{B_{ij}} - \sum_k Q_{ki} \quad (12)$$

The term  $Q_{ij}/B_{ij}$  is the apparent cross section of level  $i$ . It should be noted that branching factors are often sensitive to the scheme of generation and should be avoided when possible by determining the total cross section with actual measured sums of optical cross sections (Ref. 4:14).

Calculation of cross sections by use of photon flux is also troublesome because photon fluxes are difficult to measure. The detection system will measure radiation in a particular solid angle from the observation region:

$$F_{ij} = \frac{4\pi}{\Omega} F_{ij}(\Omega) \quad (13)$$

In Equation (13),  $F_{ij}(\Omega)$  is the photon flux gathered in a certain solid angle  $\Omega$ . It will be assumed that the emitted radiation is isotropic. This is not always the case, but it simplifies the equation by disregarding polarization effects, which are negligible in many cases (Ref. 4:13). The detection system will measure a signal which is proportional to  $F_{ij}(\Omega)$ . The proportionality constant will include spectral sensitivity of the detection devices,  $S(\lambda)$ ; and the transmission factors of various optical components,  $t(\lambda)$  (Ref. 4:14).

$$I_c = t(\lambda) S(\lambda) F_{ij}(\Omega) \quad (14)$$

The signal displayed by the detector is denoted by  $I_c$ . From Equations (11), (13), and (14) it can be shown that

$$Q_{ij} = \frac{4\pi e I_c}{\Omega N \Delta x t(\lambda) S(\lambda) I} \quad (15)$$

This defines the cross section in terms of known or measurable quantities. The spectral sensitivity can be determined from a known source.

### III. APPARATUS

#### Vacuum System

The vacuum system was capable of reaching pressures as low as  $10^{-7}$  torr. All accessible tubes were wrapped with heating tape to enhance outgassing of the system during the bake out cycle. The actual pumping was accomplished by use of a mechanical forepump in series with a Welch turbo-molecular pump. The turbo-molecular pump was a model 3103 which has a pumping speed of 140 liters per second. The pressure was measured by a Baird Alpert nude gauge and a Baratron capacitance manometer. The manometer measured relative pressures between a reference getter-pumped volume and the system. All flanges had copper gaskets and the gate valve used O-rings. The gate valve was set to close automatically should the line voltage drop. This prevented contamination of the major sections of the system due to oil backstreaming from the pumps when they stopped pumping. The vacuum system is diagrammed in Figure 4 (Ref. 5).

For pressure calibration, the flow of gas in the system was stopped when the target chamber had been filled. This eliminated the need for flow equations and non-uniformity calculations on the gas. However, static conditions create danger of cathode contamination by residual oxygen. Therefore, a Saes Sorb-AC AP-ION appendage pump was used. This pump was operated at 0.6 amps and 30 volts to yield a pumping speed for oxygen of 9.2 liters per second, but did not pump the rare gas effectively.

Figure 4. Vacuum System.

### Electron Gun

A monoenergetic electron beam is desirable during the direct excitation of the gas atoms. However, it is difficult to produce a perfectly monoenergetic electron beam. The retarding-potential-difference method described later in this section will produce a narrow electron energy distribution. For the present application, an excited

state density of  $10^8/\text{cc}$  out of a total density less than  $10^{14}$  is acceptable.

The electron gun produced a one centimeter diameter electron beam to increase the observable interaction-volume and ensure adequate signal. Therefore, the signal to noise ratio was increased and the amount of possible error was decreased. The emitter was composed of porous tungsten impregnated with barium. It was heated to  $10500^\circ \text{K}$  and thus became an IR emitter. It was necessary to shield the detector to prevent this radiation from reaching the detection system; so the gun was housed in a cylindrical copper shield (refer to Appendix C). The shield was 3.75 inches in length and 3 inches in diameter. A  $1/16$  inch observation slit was cut in one side of the shield (see Figure 3). The opposite side included a  $3/16$  inch slit to prevent radiation reflection. Alcohol flowing through a coil around the housing cooled it to approximately  $-20^\circ \text{C}$  (Ref. 6). The gun housing and cooling coil were electropolished to remove sharp edges or scratches in the metallic surfaces which could trap contaminants. The electron beam was defined by a series of five grids spaced 0.050 inches apart. The grids are centered in stainless steel discs which are connected by precision-ground alumina sleeves. This technique was developed by C. K. Crawford (Ref. 7:128). The grids are made of 0.25 mm thick molybdenum mesh. A typical disc is drawn in Figure 5.

The discs are 0.020 inches thick and 5 cm in diameter. Stainless steel clips placed around the alumina rods ensured that the grids would not slide or separate. Tungsten springs were used to allow room for the components to spread when heated so as not to touch one another. Pyrex sheaths surrounded the alumina rods in the interaction region to

Figure 5. Electron Gun Grids.

prevent absorption of the radiation and to separate the grids. Alumina spacers were used to separate the other discs.

The electron gun described in the previous paragraphs was operated using a modulation technique which is capable of embracing the retarding-potential-difference (RPD) method. The RPD method was originally designed by R. E. Fox, W. M. Hickam, T. Kjeldaas Jr., and D. J. Grove (Ref. 8:859). The technique involved maintaining the intermediate electrode at a negative potential with respect to the cathode which prevented low energy electrons in the distribution from entering the target chamber. The retarding potential  $V_r$  was applied directly to a disc in the path of the electron beam. The adjacent slits were kept at a potential close to  $V_r$  to provide a uniform potential in the plane of the retarding disc.

The RPD method was revised in 1959 by G. G. Cloutier and H. I. Schiff (Ref. 9:473). They used a potential minimum in the region between the filament and the anode to produce the retarding potential.

The initial energy distribution of electrons can be calculated from Maxwell's equations. The number of electrons  $dN_s$  emitted per unit area per unit time which have velocities between  $v$  and  $v + dv$  is (Ref. 9:475):

$$dN_s = N_s \frac{mv}{kT} \exp \left[ -\frac{mv^2}{2kT} \right] dv, \quad (16)$$

where  $N_s$  is the total current density of electrons leaving the filament,  $m$  is the mass of the electrons in kilograms,  $v$  is the electron velocity in m/sec,  $k$  is Boltzmann's constant, and  $T$  is the temperature in degrees Kelvin. By making use of the fact that  $E = \frac{1}{2}mv^2$  and the differential  $dE = mv dv$ , the number  $dN_s$  can be converted to terms of energy. Equation (16) becomes,

$$dN_s = \frac{N_s}{kT} \exp \left[ \frac{-E}{kT} \right] dE, \quad (17)$$

which represents the number of electrons emitted from the filament per unit area per unit time with energies between  $E$  and  $E + dE$ . A graph of the exponential distribution is shown in Figure 6.

Figure 6. Electron Distribution (Ref. 9:477).

The electrons to the right of  $V_p$  have sufficient energy to surmount the potential barrier, but retain the same distribution.

Resulting from the need for large signals, energy resolution obtainable from the RPD method was traded for high currents obtained using a simple modulation technique. The arrangement used to obtain the desired electron currents is shown in Figure 7. Element A is the

Figure 7. Electron Gun.

cathode to which the heater current is applied; element B is termed the Accel and has the accelerating voltage applied to it. Element C is the anode and is modulated from zero to a positive voltage with respect to the cathode so that the current is biased off during one half cycle. Element D is termed the grid and is also negative with respect to the cathode; element F is termed the chamber and is at ground potential; element G is a Faraday cage and is also at ground potential; element H is the collector to which the cup voltage is applied. The distance from the Faraday cage to the Chamber is 0.6 inches. Element E insures

that the electrons have an energy at least as great as those leaving the cathode. The region between elements F and G is essentially field-free. The interaction volume is located in this region.

The wiring used to achieve the desired potentials is shown in Figure 8. Wires were fed through the faceplate (see Figure 9) inside alumina insulators and excited the chamber through a twenty pin connector. The pins of the connector were labeled alphabetically to eliminate cross wiring. The faceplate was made of 0.030 inch thick copper and was 9 cm in diameter. It was attached to the copper cooling shield by the support rod and shield connections.

Figure 8. Electron Gun Wiring.

Figure 9. Copper Shield Faceplate.

Figure 10 shows the wiring connections through a patch panel and into the power supply. The power supply used was designed by P. Bletzinger and built by P. D. Tannen (Ref. 10). An external accelerating voltage was drawn from a Fluke power supply, model 330B. Photographs of the electron gun are shown in Appendix B.

#### Detection System

The detection system included a lens to focus the emitted radiation, a monochromator, and a detector. While measuring excitation functions of visible and near IR lines, a fused quartz lens with a focal length of 10.15 cm was used. A half-meter Jarrel-Ash monochromator was used to select the chosen wavelength with a two inch square grating of 560 lines/mm giving a resolving power of 89916. The grating was blazed at  $6000 \text{ \AA}$ . An RCA photomultiplier model 31034A detected the photons in

Figure 10. Patchpanel to Power Supply.

the 3000-9000 Å region. The spectral sensitivity as a function of wavelength of the detection system is plotted in Figure 11. The PMT was biased at 1500 V and thermoelectrically cooled to  $-20^{\circ}\text{C}$  by a refrigeration chamber model TE-104 TS RI. The signal counts were electronically divided by the electron current to compensate for the change in radiation intensity as a function of electron current as shown in Figure 14. Therefore, the response of the detection system is linear in the desired region and comparison of line intensities gives relative cross sections.

Figure 11. Spectral Sensitivity of Detection System.

A block diagram of the apparatus is shown in Figure 12. A signal generator modulates the electron beam to enable discrimination of the light output from the background noise. The light from the observation volume was collected by a lens and focused into the monochromator. Light coming through the monochromator fell on a PMT. The signal was then fed into a narrow-band amplifier and interpreted by a phase-sensitive detector. This information was divided by the electron current and fed into the Y input of an X-Y plotter which plotted this signal against electron energy applied to the X input. Refer to Appendix A for operating procedure.

#### IV. EXPERIMENT

##### Linearity Checks

A certain amount of energy smearing occurs in the energy of the electron beam. It is desirable to have a minimum amount of energy spread to ensure adequate determination of electron energy. To check the electron beam energy profile, a series of slits was placed at different heights along the monochromator slit. The intensity was examined at different locations along the diameter of the electron beam. This was done to ensure that the energy spread of the electron beam energy was below 5% from the peak energy (See Figure 13).

It is desirable to have the output signal generated from electron-atom collisions where the electron energy is known. Therefore, it is necessary to ensure that the electrons suffer no other collisions. Thus, it is assumed that if less than one percent of the electrons in the beam suffer inelastic collisions, then the amount of current lost would be negligible:

$$I_c = N\Delta x Q I \quad , \quad (18)$$

where  $I_c$  is the collisional current,  $N$  is the number density,  $\Delta x$  is the width of the observational volume,  $Q$  is the total cross section, and  $I$  is the total current. For the criterion above:

$$\frac{I_c}{I} \leq 0.01 \quad (19)$$

Substituting Equation (18) into Equation (19) yields,

$$N\Delta x Q \leq 0.01 \quad . \quad (20)$$

Figure 13. Electron Beam Energy. Measured at various distances along beam diameter.

With a known observational width and an approximate cross section the approximate number density can be obtained (Ref. 1:12). For the system described, the observational width is 1/16 inch and the cross section is approximately  $10^{-15} \text{ cm}^2$ . Plugging these numbers into Equation (20) and solving for the number density yields:

$$N \approx 4.064 \times 10^{14} \frac{\text{atoms}}{\text{cm}^3} . \quad (21)$$

#### Signal vs. Pressure

Certain tests must be performed to demonstrate linearity of the detection system. The first test is to measure signal versus pressure holding electron current, accelerating voltage, and all other parameters

Figure 14. Signal vs. Pressure.

constant. The accelerating voltage should be placed far away from the excitation peak to avoid radical signal changes for small shifts in electron energy. A linear response in signal vs. pressure implies that the signal arises from electron-atom collisions, in accord with Equation (1). As the pressure is increased and more atoms are available in the target chamber, then the signal should increase. This test proved to be linear from  $2.4 \times 10^{-4}$  torr to  $9.6 \times 10^{-4}$  torr which is in the working limits of this experiment. The results from this test are displayed in Figure 14. The linearity of this test ensures that the gas density does not increase enough so that a single electron will make multiple collisions and that atom-atom collisions will not occur with consequent energy exchange. If a single electron were to make multiple collisions then the graph would not increase linearly with pressure. The line would rise exponentially as pressure increased if atom-atom collisions cause energy transfer. Since linearity is evident in the graph, changes in pressure will affect intensities of excitation functions only by a linear factor. The cross sections, however, will not be affected because of the number density term in the formulas, providing that the pressure was known and remained constant during individual runs.

#### Signal vs. Current

The signal was also measured as a function of electron current to test for linearity. The electron current was changed by varying the drawout potential of the electron gun. Pressure, accelerating voltage and all other parameters were held constant. The accelerating voltage was set at a high voltage (95 V) for the same reason as in the signal versus pressure test, namely to avoid radical signal changes for small shifts in electron energy. The signal versus current test ensures that

no appreciable multiple excitations occur in the observation region. The results are given in Figure 15. The linearity of this graph shows that the collected radiation intensity was directly proportional to the electron current. Therefore, the signal was divided automatically by the current to compensate for changes in the electron current. The deviation from linearity at currents greater than 250  $\mu$ amps results from energy loss due to electron-electron collisions. Only currents in the linear portion of this graph were used to collect data.

#### Comparison to Previous Measurements

Excitation functions for helium transitions have been measured by previous researchers and are well known. Therefore, remeasurement of some of these excitation functions provide a suitable test for the accuracy of the apparatus. The initial attempt proved futile because the signal-to-noise ratio was low and the shape of the excitation function was indeterminable. Since the signal was visible with the naked eye and the dark room provided no appreciable noise level, it was deduced that the entire signal was not being collected. Alignment of the optical detection system decreased the noise level and concurrently increased the signal strength. When the excitation function of the He  $3889 \text{ \AA}$  transition was then obtained, it was found to have a shape disagreement with previously published data. Figure 16 shows a comparison of the result from the initial measurement of this work to the shape measured by I. P. Sapesochnyi and P. V. Felstan (Ref. 11). The rise in the excitation function at high energy was suspected to result from focusing of the electron beam as a function of accelerating voltage, coupled with inadequate optical collection of the observation volume.

Figure 15. Signal vs. Current.

Referring to Figure 3, this means that the area of observation  $h\Delta x$  is larger than the area of the monochromator slit. Equation 3 dictates that the entire area through which electrons pass must be collected by the optics in order to accurately describe the physical interaction which is the subject of research. The detection system up to this point was aligned so that there was unit magnification of the image of the electron beam on the slits of the monochromator. In order to correct for inadequate collection of the image, the system was realigned using magnification of one half. Therefore, the monochromator slit height of 1 cm is approximately a factor of two larger than the image of the 1 cm diameter electron beam. The excitation function for the  $3889 \text{ \AA}^0$  transition measured subsequent to the magnification reduction is displayed in Figure 17. The results of I. P. Zapesochnyi, J. H. Lees (Ref. 12), F. L. Miller (Ref. 13), and H. R. M. Moussa (Ref. 14), shown in Figure 18, were used as a basis for determining the accuracy of the apparatus. The data obtained in this work is comparable to I. P. Zapesochnyi's result.

## V. STANDARDIZATION

### Transmission Factors

The detection system must be standardized to make absolute measurements. The standardization procedure consists of determining the spectral sensitivity of the detectors by use of a calibrated tungsten ribbon lamp. The solid angle of radiation which is gathered by the lens is given by:

$$\Omega = \frac{\pi R^2}{S_0^2} \quad (22)$$

where  $R$  is the radius of the lens and  $S_0$  is the object distance. A magnification of  $\frac{1}{2}$  was obtained by setting  $S_0$  equal to twice the length of  $S_1$  (see Figure 19). This ensures that the entire image will fall on the monochromator slit. The lens radius is 3.0 cm, the object distance is 40.0 cm, and therefore the solid angle is  $1.77 \times 10^{-2}$  str. The slit width,  $w$ , of the monochromator will be the length of the observation region,  $\Delta x$ . The radiation must pass through the chamber window and the lens. These optical elements have transmission factors given by  $t_w$  and  $t_L$  respectively. The transmission factor for the monochromator is given as (Ref. 16:25),

$$t_M = \begin{cases} 1 + \frac{\lambda - \lambda_0}{\Delta\lambda} & \text{for } \lambda_0 - \Delta\lambda \leq \lambda \leq \lambda_0 \\ 1 - \frac{\lambda - \lambda_0}{\Delta\lambda} & \text{for } \lambda_0 \leq \lambda \leq \lambda_0 + \Delta\lambda \end{cases} \quad (23)$$

where  $\Delta\lambda$  is the monochromator bandpass and  $\lambda_0$  is the peak of the transmission function. These values are further illustrated in Figure 20.

The entrance and exit slits must be equal in order for the above conditions, including Equations (22) and (23), to hold. The Jarrel-Ash

Figure 19. Optical Pathlengths.

Figure 20. Monochromator Transmission Factor versus Wavelength.

half meter monochromator has a bandpass of  $8 \text{ \AA}$  at  $6000 \text{ \AA}$  for slit widths of 400 microns.

For simplification in standardization procedures, a standard lamp source was measured at a wavelength of  $6000 \text{ \AA}$ . In this case, the transmission factor of the monochromator is unity, which results in maximum intensity. The cross section can then be written using Equations (15) and (22):

$$Q_{ij} = \frac{4 S_o I_c e^2}{R^2 \Delta x N I t_w t_L S(\lambda)} \quad (24)$$

### Calibration

In order to calculate the spectral sensitivity, a General Electric standard lamp type GE 30A/T24/7 was used in the standardization procedure. It has a tungsten ribbon filament located approximately 10 cm. behind a fused silica output window. The output window is three centimeters in diameter.

The spectral radiant flux,  $P_\lambda$ , of the standard lamp is given by,

$$P_{\lambda} = R_{\lambda} N_{\lambda} s A / D^2 \quad ; \quad (25)$$

where,

$R_{\lambda}$  = spectral reflectance of combination of mirrors (0.84)

$N_{\lambda}$  = spectral radiance of standard (50.00  $\mu\text{W}/\text{str-m}^{-2}$  at 6000  $\text{\AA}$ )

$s$  = area of spectrometer slit (2.25  $\text{mm}^2$ )

$A$  = area of limiting optic (706.9  $\text{mm}^2$ )

$D$  = distance of optic from slit (400 mm).

Therefore the spectral radiant flux of the standard lamp at 6000  $\text{\AA}$  is 64.8  $\mu\text{W}/\text{m}^2$ .

To ensure that the solid angles and optical path lengths of the standard lamp and collision chamber are essentially equal, it was decided that the monochromator, detector, and imaging lens be placed on a movable table. The table could be moved in a direction perpendicular to the optical paths of radiation. The standard lamp was mounted beside the collision chamber so that the optical paths were parallel. The standardization arrangement is shown in Figure 21.

The output of the photomultiplier tube (PMT) in the standardization configuration is given by Walker (Ref. 4:28) as:

$$I_S = S(\lambda) A_S \Omega_S t_S t_L \int_{\lambda_0 - \Delta\lambda}^{\lambda_0 + \Delta\lambda} R_N(\lambda, T) t_m d\lambda \quad , \quad (26)$$

where,

$A_S$  = area of tungsten ribbon from which photons are collected by the monochromator

$\Omega_S$  = solid angle from which light is collected in the standardization arrangement

Figure 21. Standardization Configuration.

$t_S$  = transmission factor of the standard lamp window

$R_N(\lambda, T)$  = photon radiancy.

The photon flux hitting the detector,  $F_S$ , can be defined as,

$$F_S = A_S \Omega_S t_S t_L \int_{\lambda_0 - \Delta\lambda}^{\lambda_0 + \Delta\lambda} R_N(\lambda, T) t_m d\lambda ; \quad (27)$$

which simplifies Equation (26) to,

$$I_S = S(\lambda) F_S \quad (28)$$

The photon radiancy gives the rate of photon emission per unit wavelength interval into unit solid angle normal to the surface whose temperature is  $T$ . The tungsten can be approximated as a graybody (Ref. 4:29) because,

$$R_N(\lambda, T) = e(\lambda, T) R_N^B(\lambda, T) \quad , \quad (29)$$

where  $e(\lambda, T)$  is the emissivity of the tungsten ribbon and  $R_N^B(\lambda, T)$  is the blackbody photon radiancy.

St. John (Ref. 17:30) shows that division of power radiancy,  $I_N^B$ , by  $hc/\lambda$  gives photon radiancy:

$$R_N^B(\lambda, T) = I_N^B(\lambda, T) \frac{\lambda}{hc} \quad . \quad (30)$$

The power radiancy is given by the expression,

$$I_N^B = \frac{2hc^2}{\lambda^5} \frac{1}{(e^{hc/\lambda KT} - 1)} \quad , \quad (31)$$

which means,

$$R_N^B(\lambda, T) = \frac{c_1}{\pi hc \lambda^4} \frac{1}{(e^{c_2/\lambda T} - 1)} \quad (32)$$

where

$$\begin{aligned} c_1 &= 3.7405 \times 10^{-16} \text{ W-m}^2 \\ c_2 &= 1.43879 \times 10^{-2} \text{ m}^{\circ}\text{K} \quad . \end{aligned}$$

The integral in Equation (26) for a  $\Delta\lambda$  of  $16 \text{ \AA}$ ,

$$R_{16}(\lambda_0, T) = \int_{\lambda_0 - 16 \text{ \AA}}^{\lambda_0 + 16 \text{ \AA}} R_N^B(\lambda, T) e(\lambda, T) t_m d\lambda \quad , \quad (33)$$

has been calculated by J. D. Jobe (Ref. 18:14) to be approximately

$$R_{16}(\lambda_0, T) = \frac{16 \overset{0}{A}}{\Delta \lambda} e(\lambda, T) R_{\Delta \lambda}^B(\lambda_0, T) \quad (34)$$

The emissivity  $e(\lambda, T)$  is a slowly varying function of wavelength and was, therefore, assumed to be constant. Equation (34) is good within one percent for values of  $\Delta \lambda < 100 \overset{0}{\text{\AA}}$  if  $T < 3000^\circ \text{K}$  and  $\lambda_0 > 2200 \overset{0}{\text{\AA}}$ . Only the linear terms in the Taylor expansion for  $R_N^B(\lambda, T)$  about  $\lambda_0$  were integrated over. Using Equations (27) and (28) with Equation (34) produces

$$S(\lambda) = \frac{16 \overset{0}{A} I_s}{A_s \Omega_s t_s t_L \Delta \lambda e(\lambda, T) R_{16}^B(\lambda, T)} \quad (35)$$

Combining this with Equation (22) yields,

$$Q_{ij} = \frac{4 S_o^2 I_c e^{\Delta \lambda} e(\lambda, T) R_{16}^B(\lambda, T) t_s}{16 \overset{0}{A} I_s \text{INT}_w R_{\Delta \lambda}^2} \quad (36)$$

The chamber window is composed of sapphire and the standard lamp window is fused silica. The transmission factor for both windows is fairly constant over the wavelength region examined. The transmission factor for sapphire is approximately 82% and that of fused silica is 90%. Therefore, the ratio of transmission factors,

$$\frac{t_s}{t_w} = 0.91 \quad , \quad (37)$$

and, therefore,

$$t(\lambda) = 0.74 \quad . \quad (38)$$

## VI. CONCLUSION

### Technique Improvements

Two critical considerations in electron gun design are the mounting of the insulating feed through in the faceplate of the copper shield and the gold plating of the copper shield. The wires which were used to apply potentials to the electron gun grids were fed through the copper faceplate in alumina insulators. The insulators were initially mounted in the copper shield with epoxy. The heat produced during the activation process caused the epoxy to burn. An oxide was produced and deposited on the alumina insulators, thus shorting out the electron gun. Careful investigation resulted in the use of Ceramabond, an alumina based cement, as a replacement for epoxy.

The gold plating of the copper shield was an attempt to prevent oxidation of the shield and to deter absorption in the infrared. However, the gold was also affected by the heat of activation. As the shield became hot, the gold diffused into the copper. Examination of the properties of gold showed that the shield must be cooled when the heater current is greater than one amp. The temperature increase due to the filament is sufficient to cause gold to diffuse into copper and to burn epoxy.

The copper shield completely surrounded the electron gun and, thus, radiation was scattered from the inside walls of the shield. This radiation reflected through the observation slit. In attempts to align the monochromator, reflected radiation created a large background signal. An attempt was made to minimize the noise by cutting a 1/16 inch slit opposite the observation slit. Nevertheless, significant reflection

occurred, so the gun was removed and the opposite slit was enlarged to 3/16 inch. The reflected radiation was reduced, but a small amount was still detectable.

### Results

All results were taken in the regions where the output radiation was proportional to the pressure and the electron gun current. The appearance potential in all cases was found to be within 2 eV of the spectroscopic value published in Striganov and Sventitski (Ref. 19:571). However, the relative intensities shown in the tables do not compare with those shown here. There is a difference between relative intensities of various lines excited by a discharge and those excited by a monoenergetic electron beam (Ref. 20:4). Therefore, tabulated intensity ratios are insufficient for interpretation of the xenon spectrum. Generally, excitation functions for xenon I lines have maximum cross sections at energies between 16 eV and 22 eV. An example is shown in Figure 22. This figure shows the actual data obtained by the experimental configuration shown in Figure 12. These lines have sharp peaks at the maximum and slope downward at higher electron energies, Figure 23 shows an excitation function with a maximum at an electron energy between 16 eV and 22 eV, but the cross section remains approximately constant at higher energies. The characteristic shape of the excitation function has been extracted in order to eliminate possible confusion resulting from scale changes and minute line divisions on the raw data. Some excitation functions have a slight "hump" around 30 to 70 eV. This "hump" in most cases is probably caused by cascading from higher states. As the electron energy is increased, the bombarding electrons may excite

Figure 22. Xe 4697 Å ( $7p [1/2] \rightarrow 6s [1/2]$ )

Figure 23. Xe 7336 Å ( $5d' 2\frac{1}{2} \rightarrow 6p [2\frac{1}{2}]^o$ )

levels at higher energies than the level we are observing. These atoms in higher excited levels make a series of energy level transitions to eventually reach the ground state. Thus, the energy level we are observing may be populated following decay from atoms excited to higher states, as well as from direct excitation of ground state atoms. This former process is called cascading and an example of this can be seen especially well as a hump from 40 - 90 eV on the excitation function for the  $6318 \text{ \AA}^0$  transition shown in Figure 24. The apparent drop in cross section at 15 eV was due to a change in scale which was not manually adjusted at the proper time.

Figure 23 ( $5d'[2\frac{1}{2}]^0 \rightarrow 6p[2\frac{1}{2}]^0$ ) and Figure 24 ( $8d[3\frac{1}{2}]^0 \rightarrow 6p[2\frac{1}{2}]^0$ ) show excitation functions for transitions from d levels and both exhibit sharp peaks. These figures also show that d level transitions have large cascade contributions.

Generally broader excitation functions have maximum cross sections at electron energies greater than 25 eV. The s level transitions appear to have broadly peaked excitation functions as displayed by Figure 25 ( $8s[1\frac{1}{2}]^0 \rightarrow 6p[2\frac{1}{2}]^0$ ). This excitation function for the  $7803 \text{ \AA}^0$  transition has a step or plateau at electron energies near 20 eV. The contribution due to cascading overlaps the direct excitation contribution. Therefore, the initial rise is due to the direct contribution to the level being examined and the "hump" results from cascading effects. Figure 26 shows the excitation function for the  $8576 \text{ \AA}^0$  transition which has two maxima: a sharp peak at 15 eV and a broader peak at 27 eV. The excitation function for the  $4807 \text{ \AA}^0$  transition shown in Figure 27 also has a double peak, but the peaks are spaced only 1.5 eV apart. These double peaks are also believed to be a result of cascading.

Figure 24. Xe 6318 A ( $8d [3\frac{1}{2}]^o \rightarrow 6p [2\frac{1}{2}]^o$ )

Figure 25. Xe 7803 Å ( $8s[1\frac{1}{2}]^{\circ} \rightarrow 6p[2\frac{1}{2}]^{\circ}$ )

Figure 26. Xe 8576 A ( $7p[\frac{1}{2}] + 6s'[\frac{1}{2}]^{\circ}$ )

Figure 27. Xe 4807 Å ( $7p[1/2] \rightarrow 6s[1 1/2]^{\circ}$ )

The shapes of all excitation functions depend only upon the characteristics of the ground state and the upper excited state. The shapes can be predicted by use of the Born Approximation and the resulting relation:

$$Q_{01} = 2 \pi \int_0^\pi \left\{ \int_0^\pi \psi_0 e^{i(k_0 - k_1)r_1} \psi_1^* dr \sin\theta d\theta \right\}, \quad (39)$$

where  $\psi_0$  is the wavefunction for the ground state,  $k_0$  and  $k_1$  are the wavenumbers for the respective states,  $r_1$  is the separation distance, and  $\psi_1$  is the wave function for the excited state (Ref. 21:436).

The data obtained shows that the d level transitions have sharply peaked excitation functions and the s level transitions appear to have more broadly peaked excitation functions. However, the p level transitions have excitation functions with shapes which seem to vary according to the value of the angular momentum J of the upper level. The excitation functions for upper level J values of one, two, and three are sharply peaked. An excitation function for J=1 is shown in Figure 28. Figures 29-32 display sharply peaked excitation functions for J=2. Examples of excitation functions for upper levels with values of J=3 are presented in Figures 33 and 34. However, excitation functions for transitions from upper excited levels which have zero angular momentum are more broadly peaked. Figures 35 and 36 show examples of the broad excitation functions for p level transitions.

An analysis of the coupling scheme which best describes the xenon excitation cross sections was felt to be beyond the scope of this work. No comparison with helium is made because helium subscribes well to LS coupling, while xenon is better described by j $\ell$  coupling (Ref. 22:537).

Figure 36. Xe 7887 Å ( $6p' [1/2]^\circ \rightarrow 6s' [1/2]^\circ$ )

It is generally expected that transitions which are allowed by quantum mechanics selection rules will be more intense and have broader excitation functions than those transitions which are forbidden. The sharper excitation functions represent triplet transitions which are not allowed by quantum mechanics selection rules because a spin flip of one of the orbital electrons is required. A singlet transition which requires no spin flip is an allowed transition and, therefore, has a broader excitation function. However, heavier noble gases (i.e., krypton and xenon) have wavefunctions which are a combination of singlet and triplet basis functions. The shapes of these excitation functions depend upon the relative weights of the basis functions. It has been observed by Sharpton et. al (Ref. 23:1305) that in the case of neon, with a  $2p^6$  ground state, that for a given configuration  $2p^5n\ell$ , the states with odd values of  $J+1$  have larger cross sections than states with even values of  $J+1$ . The following observations are made for the present results for xenon. The transitions from the d levels show sharp peaks and large peak cross sections. The  $5d'$  transitions have greater intensities than the transitions from the  $8d$  level. The s level transitions appear to have more broadly peaked excitation functions and the peak cross sections are of average intensity compared to transitions from other levels.

The p levels seem to show both broad and sharp peaks in the excitation functions depending upon the value of the angular momentum J. The intensities of the p level transitions also vary according to the value of J. The intensities of the peak cross sections are shown in Appendix B. The transitions above the dotted line have sharply peaked excitation functions, while those below the line are broader. Those

transitions from upper excited levels with angular momentum values of one or two have peak cross sections which are weak. The lowest peak cross section was obtained from the  $4501\text{ Å}^0$  transition from the 6p level with  $J=2$ . The value of the cross section for the transition is  $3.79 \times 10^{-20}$ . Transitions from upper p levels with  $J=0,3$  appeared to have more intense peak cross sections. The strongest cross section was found in the  $8819\text{ Å}^0$  transition from the 6p level which had a value of three for the angular momentum. The only discrepancy for these assumptions is for the intensity of the peak cross section for the  $8231\text{ Å}^0$  transition which was much greater than that predicted. However, the double peak implies entrapment of resonance radiation and/or cascade overlap which tend to increase the intensity.

The pressures and electron gun energies used were sufficient to create xenon II lines in some cases. These lines result from ionization of the xenon gas atoms. In certain cases, the xenon II lines have wavelengths within  $4\text{ Å}^0$  of the xenon I wavelengths. The xenon II lines have maximum cross sections at electron energies between 30 eV and 50 eV. If the monochromator slit is 400 microns wide, then these lines are unresolvable. The result on excitation functions for xenon I lines is a large "hump" with a maximum between 30 eV and 50 eV. This large "hump" has a threshold which is approximately 26 eV, and therefore, is not obviously the result of cascading effects. Figure 37 shows this effect on the excitation function for the  $4923\text{ Å}^0$  transition. The excitation function for the xenon I transition at  $4843\text{ Å}^0$  also shows this effect as seen in Figure 38. Examination of spectral lines for xenon II transitions (Ref. 19:581) yields no evidence for a xenon II line at  $4923 \pm 4\text{ Å}^0$ .

Figure 37. Xe 4923 Å and Unknown 4927 Å

Figure 38.  $\text{Xe } 4843 \text{ \AA}$  and  $\text{Xe}^+ 4844 \text{ \AA}$

however, a xenon II line at  $4844 \text{ \AA}$  does exist. Therefore, the double maximum on  $4843 \text{ \AA}$  excitation function is evidently a result of observing two lines, a xenon I line and a xenon II line. The large "hump" for the  $4923 \text{ \AA}$  transition appeared to be too large for cascading effects, so the monochromator slits were reduced to 150 microns and a spectrum was taken around  $4923 \text{ \AA}$  at 45 eV. The results displayed in Figure 39 show an unidentified line at  $4927 \text{ \AA}$ . These lines are separated by  $1.64 \text{ \AA}$  at half maximum. The excitation functions for the  $4923 \text{ \AA}$  and  $4927 \text{ \AA}$  lines were examined using 150 micron slits. Figure 40 shows the excitation function for the  $4923 \text{ \AA}$  line and Figure 41 gives the excitation function for the unidentified line at  $4927 \text{ \AA}$ . Although the unidentified spectral line could be that of an impurity, no other evidence of impurities was discovered. In addition, the threshold and characteristic shape of the excitation function for the  $4927 \text{ \AA}$  line were similar to those of xenon II lines measured in this work. Therefore, this spectral line is presumed to be a previously unidentified xenon II line.

Other lines (i.e.,  $4670 \text{ \AA}$  and  $4807 \text{ \AA}$ ) have small "humps" which can be explained by cascading effects, but could also be a result of contributions from xenon II lines (i.e.,  $4672 \text{ \AA}$  and  $4806 \text{ \AA}$  respectively). Figure 42 shows the excitation function for the  $4843 \text{ \AA}$  transition, which is a xenon I transition. The shape of the xenon II transition is given in Figure 43 for  $4844 \text{ \AA}$ . Most xenon II transitions have peak cross sections at electron energies around 40 eV.

### Error Analysis

The error in the energy of the electrons is due to an energy spread in the electron distribution and a potential shift. The poten-

tial shift may be measured as the difference between the spectroscopic value for the onset of excitation and the observed value, and is correctable to 0.1 eV. The energy spread is approximately 1.5 eV at electron energies less than the ionization potential for xenon (12.1 eV). The energy spread increases to about 2.5 eV when an energy greater than that necessary for ionization is reached.

The governing equation for the cross section is given by Equation 15. The parameters which have non-varying errors are  $\Omega$ (3%),  $\Delta x$  (1%),  $t(\lambda)$  (1%), and  $S(\lambda)$  (2%). The error in the number density  $N$  may be determined by the gas law:

$$PV = NRT \quad (40)$$

The errors in the volume and temperature are 2% and 5% respectively. The error in the pressure arises from the calibration of the pressure gauge, the distance of the gauge from the interaction volume, and a slight gas flow through the interaction region. A combination of these errors gives an error in pressure up to 5%. Therefore, the error in the number density is 7%. The parameters which vary significantly and thus have varying errors are the signal  $I_c$  and the electron current  $I$ . The signal has statistical deviation which varies from 1% to 11% depending upon the intensity of the signal and the noise level for the particular day of measurement. The highest percentage error was noticed in Figure 29 for the  $4501 \overset{0}{\text{\AA}}$  transition, where the error was 17% at the peak cross section and 15% at the cross section for 70 eV. The lowest error was obtained in Figure 34 for the  $8819 \overset{0}{\text{\AA}}$  transition, where the error was 8% for the peak cross section and 9% for the cross section at 60 eV. Error bars are used to show the possible error in all excitation

functions. In those instances where the error varies more than 2% over the entire energy range, error bars are displayed for the peak cross section and a cross section at a higher electron energy (usually 60-70 eV).

The shapes and peak intensities of the excitation functions obtained in this work were compared, where applicable, to those obtained by P. V. Felstan and I. P. Zapesochnyi (Ref. 24). The shapes were comparable and the peak intensities were within the percentage errors outlined in this paper. The discrepancies between this work and previous results probably arise from the use of improved instrumentation and the resulting improvements in signal strength and spectral resolution.

#### Recommendations

Further studies should be made on static operation of barium implanted cathodes. Techniques (i.e., appendage pumps) should be improved to prevent contamination of the cathode from residual oxygen.

Cascading effects on high intensity laser lines should be investigated. The cascading transitions and their relative cross sections should be determined for various electron energies between zero and 100 eV.

High resolution should be obtained for the purpose of identifying previously unresolvable lines and cascading transitions which result in "humps" or double peak excitation functions.

APPENDICES

## APPENDIX A

### START UP/SHUT DOWN PROCEDURE

Once the pressure in the system has reached  $10^{-7}$  torr range, the electron gun can be activated. Current is applied to the heater filament in increments of 50 milliamps every 15 minutes until a heater current of 1 amp was reached. The electron gun will be outgassing in this range and, therefore, the cooling system for the gun must not be turned on until outgassing is completed. If the cooling system were on, then the impurities would accumulate on the coldest portions of the copper shield and tubing. Once one amp current has been reached, the pressure should be approximately  $1 \times 10^{-7}$  torr and stable; which indicates that outgassing is completed.

The heater current was then increased in increments of 100 milliamps every 15 minutes until an operating current of approximately 4.50 amps was reached. Electron current was first detected at 4.00 amps of heater current.

Once the electron gun had been activated, gas was allowed to flow into the system until the pressure reached  $1 \times 10^{-4}$  torr. The gate valve was then closed and the interaction volume was sealed off by closing the gold seal and butterfly valves.

The detection system then needed to be turned on. First, the cooling to the PMT was set at  $-20^{\circ}\text{C}$ . The room lights were then turned off, and the PMT amplifiers were turned on. The PMT was operated at a total divider potential of 1500 V. The photon counter was then set to display the signal at one count per second. The signal was fed into

the Y-axis of the X-Y recorder after being divided by the current. The electron energy was plotted on the X-axis and was swept at 0.1 eV/sec. The monochromator was tuned to a specific wavelength and the X-Y recorder plotted the excitation function.

APPENDIX B  
TABULATION OF DATA

$\lambda^0$ (Å)	Transition	J	$Q_{ij}(\text{cm}^2)$
4697	$7p[1/2] \rightarrow 6s[1/2]^o$	2→2	$9.60 \times 10^{-20}$
7336	$5d'[2/2] \rightarrow 6s[2/2]^o$	3→2	$2.83 \times 10^{-18}$
6318	$8d[3/2] \rightarrow 6p[2/2]^o$	4→3	$5.42 \times 10^{-19}$
4830	$7p[2/2] \rightarrow 6s[1/2]^o$	1→1	$1.21 \times 10^{-19}$
4501	$6p'[1/2] \rightarrow 6s[1/2]^o$	2→1	$3.79 \times 10^{-20}$
4734	$6p'[1/2] \rightarrow 6s[1/2]^o$	2→1	$6.56 \times 10^{-20}$
8231	$6p[1/2] \rightarrow 6s[1/2]^o$	2→2	$5.46 \times 10^{-18}$

Vita

Mark Douglas Stephen was born in Castle A.F.B., California on 24 April 1956. He graduated from Summerville High School in Summerville, South Carolina on 31 May, 1974. While attending college, he joined Air Force ROTC and was commissioned on 12 May 1978. He graduated the following day from the University of South Carolina with a Bachelor's Degree in Physics. His first active duty assignment was to the Air Force Institute of Technology at Wright-Patterson A.F.B., Ohio.

20. ABSTRACT (Continue on reverse side if necessary and identify by block number) Electron impact excitation functions have been measured in xenon for excitation of some of the 6p, 6p', 7p', 8s, 5d', and 8d levels. A one centimeter diameter electron beam was used to excite the gas atoms. The beam was made nearly mono-energetic by use of the retarding-potential-difference method. Most of the xenon I excitation functions were sharply peaked around 18 eV. Broader excitation functions were measured which had peak cross sections at electron energies around 30 eV. Cascading from higher energy

BLOCK 20 (Cont'd)

levels showed significant effects on selected optical excitation functions. The electron gun produced a current of approximately one milliamp. Measurement of some xenon II excitation functions produced by simultaneous ionization/excitation were obtained. The xenon II excitation functions demonstrated a maximum at approximately 35 eV, and a broader shape than the Xe I excitation functions.
